15 **Abstract**

16 Our food system drives global environmental change, and differences in environmental concerns of
17 consumers may cause negative environmental 'spillover effects' in less concerned countries. Using
18 an integrated environmental-economic modelling framework and scenario analyses, we explored
19 options for more sustainable food systems and to mitigate the negative environmental spillovers
20 from trading partners to China. We found that doubling soy-based food (SBF) consumption while
21 reducing pork consumption in China decreased Chinese economy-wide emissions of greenhouse
22 gases (GHGs) by 1% and acidification pollutants by 3%. However, it increased Chinese economy-
23 wide emissions of eutrophication pollutants by 2%, driven by the increased SBF and other food
24 production with relatively high emission intensities of eutrophication pollutants. Combining a
25 dietary shift with the adoption of cleaner cereals production technology for half of the current
26 resources used for cereals production decreased Chinese economy-wide emissions of GHGs by 1%,
27 acidification pollutants by 7%, and eutrophication pollutants by 3%, but required capital reallocation
28 from other sectors. Implementing a unilateral environmental policy in China (i.e., implementing
29 economy-wide taxes on emissions to reduce emissions of all pollutants by 3%) increased economy-
30 wide emissions of GHGs in trading partners by 2%. This 'carbon leakage' emerges due to the shift
31 of production of products with relatively high emission intensities (i.e., nitrogen fertiliser and
32 livestock) from China to its trading partners through international trade. We can, therefore, draw the
33 following policy implication: achieving sustainable food production and consumption requires joint
34 efforts from consumers and producers as well as coordinated environmental policy across countries
35 in the world. Our study offers policymakers insights into designing effective policies for more
36 sustainable food systems and sheds light on trade-offs among competing environmental and
37 economic goals.

41 **1. Introduction**

42 The food-land-water-climate nexus concept arises from recurring resource crises, highlighting the
43 interconnectedness of food, land, water, and climate and their broader impacts. A nexus approach
44 aims to enhance resource utilisation efficiency, inter-departmental collaboration, and coherent
45 policy formulation (Doelman et al., 2022; Hoff, 2011). Exploring options for more sustainable food
46 systems in the food-land-water-climate nexus is one of the main global challenges (Griggs et al.,
47 2013), in particular when the demand for animal-based food (meat, milk, eggs) continues to increase
48 (FAO, 2022; UNCCD, 2017). Animal-based food has contributed to over half of the protein supply
49 to humans in developed countries during the last decades, while its consumption is rapidly
50 increasing in developing countries due to population growth, economic growth, and urbanisation
51 (FAO, 2022). Our food system, especially the production and consumption of animal-based food,
52 has impacts on climate change, ocean acidification, biogeochemical flows (nitrogen and
53 phosphorus), freshwater use, land-use changes, and biodiversity loss (Springmann et al., 2018).
54 Improving our food system is essential for realising the Sustainable Development Goals (SDGs),
55 especially SDG 2 (zero hunger), SDG 6 (clean water and sanitation), SDG 12 (responsible
56 consumption and production), and SDG 13 (climate action) (UN, 2015).

57 Differences in environmental concerns of consumers may cause negative environmental ‘spillover
58 effects’, namely, from trading partners with higher environmental concerns to the region with lower
59 environmental concerns (Hökby & Söderqvist, 2003; Latacz-Lohmann & Hodge, 2003; Zhu, 2004).
60 Food system transformation is increasingly recognised as crucial for mitigating such negative
61 environmental spillovers and achieving multi-dimensional SDGs (Doelman et al., 2022; Newbold
62 et al., 2015). For example, the EAT-Lancet Commission proposed various measures to keep food
63 systems within environmental limits while delivering healthy diets by 2050 (Willett et al., 2019).
64 These measures include dietary structure changes towards healthier and more plant-based diets,
65 improvements in technologies and management, and reductions in food loss and waste (Springmann
66 et al., 2018). Policy instruments, such as a meat tax (Funke et al., 2021) and emission restrictions
67 (Zhu, 2004; Zhu & Van Ierland, 2006; Zhu & Van Ierland, 2005), can help to implement the
68 aforementioned measures in practice. Du et al. (2018) have suggested that adopting a so-called

69 'green source trade strategy (i.e., importing food and feed from nations with low emissions
70 intensities)' can assist in the realisation of emission mitigation. While the direct environmental
71 benefits of food system transformation are well acknowledged, possible unintended negative
72 environmental consequences in other regions and/or economic sectors have received less attention.
73 For instance, resources freed from one sector may be reallocated to other sectors across the whole
74 economy and may influence other countries through international trade. Moreover, in some cases,
75 these negative environmental spillovers may outweigh the direct benefits of food system
76 transformation. However, many prior studies exploring options for sustainable food systems tend to
77 either focus solely on a specific mitigation measure or analyse a particular environmental impact
78 (mainly global warming potential) within small life cycles rather than adopting an economy-wide
79 perspective. This approach may result in a biased estimation of the environmental benefits derived
80 from food system transformation (Dandres, Gaudreault, Tirado-Seco, & Samson, 2011, 2012).

81 While the significance of acknowledging the indirect environmental impacts of food system
82 transformation is growing, there remains a lack of quantitative analyses that take an economy-wide
83 perspective to understand the synergies and trade-offs within the food-land-water-climate nexus.
84 This gap may hinder the design of effective policies for sustainable food systems on a global scale.
85 This study aims to bridge this gap by constructing an integrated environmental-economic modelling
86 framework based on applied general equilibrium (AGE) models and employing this framework to
87 analyse potential options for food system transformation that align with both environmental and
88 economic goals. We have chosen the AGE models for our study because AGE models with a highly
89 structured and comprehensive description of the economy based on microeconomic theory are
90 widely used to assess the economy-wide effects (i.e., production, consumption, and trade) of policy
91 changes and shock events in society (Gatto, Kuiper, & van Meijl, 2023; Mason-D'Croz et al., 2022;
92 Mason-D'Croz et al., 2020; Xie et al., 2018; Yao, Zhang, Davidson, & Taheripour, 2021). Moreover,
93 policymakers can use the AGE models to evaluate the potential socioeconomic and environmental
94 consequences of food system transformation, which, in turn, allow for feedback to enhance policy
95 design. We chose the AGE modelling approach for two reasons. First, due to the significant global
96 implications of supply-side and demand-side measures, as well as environmental policies, facilitated
97 by international trade of food and feed across various countries, our analysis necessitates a model

98 encompassing multiple countries. Second, given the intricate interconnections between food and
99 feed sectors, including intermediate uses and resource competition (e.g., land, water, and fertiliser),
100 employing a multi-sectoral model is essential for this analysis. In short, these considerations point
101 to the use of a multi-country and multi-sectoral economic model that can simulate the effects of the
102 food system transformation across the whole economy. We, therefore, developed a global
103 comparative static AGE model, a modified version of an integrated environmental-economic model
104 (Zhu & Van Ierland, 2004, 2012; Zhu, van Wesenbeeck, & van Ierland, 2006), and calibrated this
105 model with the Global Trade Analysis Project (GTAP) database (GTAP, 2014). The GTAP database
106 covers economic data of 65 sectors and 141 countries, and it has been widely used for analysing
107 global issues related to international trade, the environment, and climate change.

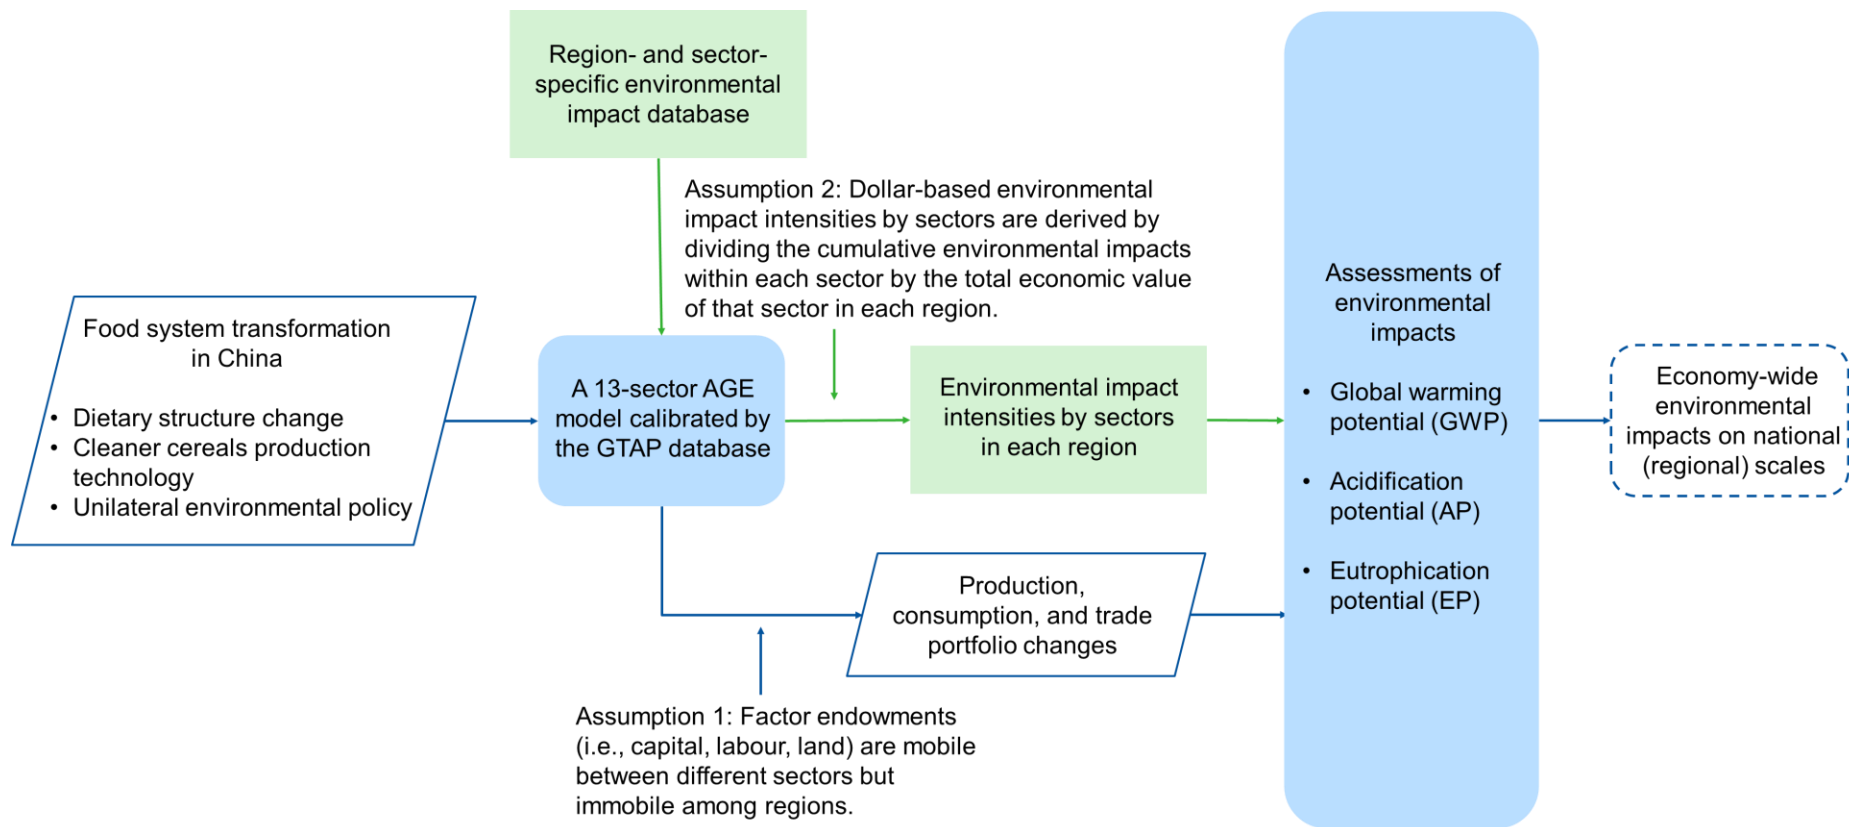

108 Our study aims to address two related questions under food system transformation. First, what are
109 the environmental and economic impacts of various options for food system transformation in China?
110 Second, what are the 'spillover impacts' on China's main food and feed trading partners through
111 international trade under the food system transformation? We took China as an example, as China
112 is among the largest and most populous countries in the world, and its food system exerts enormous
113 impacts on the environment (FAO, 2022). We apply the integrated environmental-economic model
114 to discuss how differences in environmental concerns of consumers in different regions may cause
115 negative environmental 'spillover effects', namely, from trading partners with higher environmental
116 concerns to China. To explore options for sustainable food systems to mitigate negative
117 environmental spillovers, four options for food system transformation related to emission mitigation
118 in China are simulated: (i) doubling soy-based food consumption while reducing pork consumption,
119 (ii) adopting cleaner cereals production technology for half of the current resources used for cereals
120 production, (iii) combining dietary structure change with cleaner cereals production technology, and
121 (iv) implementing economy-wide taxes on emissions to contribute to China's emission reduction
122 target and other environmental policies. We also perform a sensitivity analysis for key
123 environmental, economic behavioural, and technological parameters.

124 **2. Materials and methods**

125 2.1 The integrated environmental-economic model and database

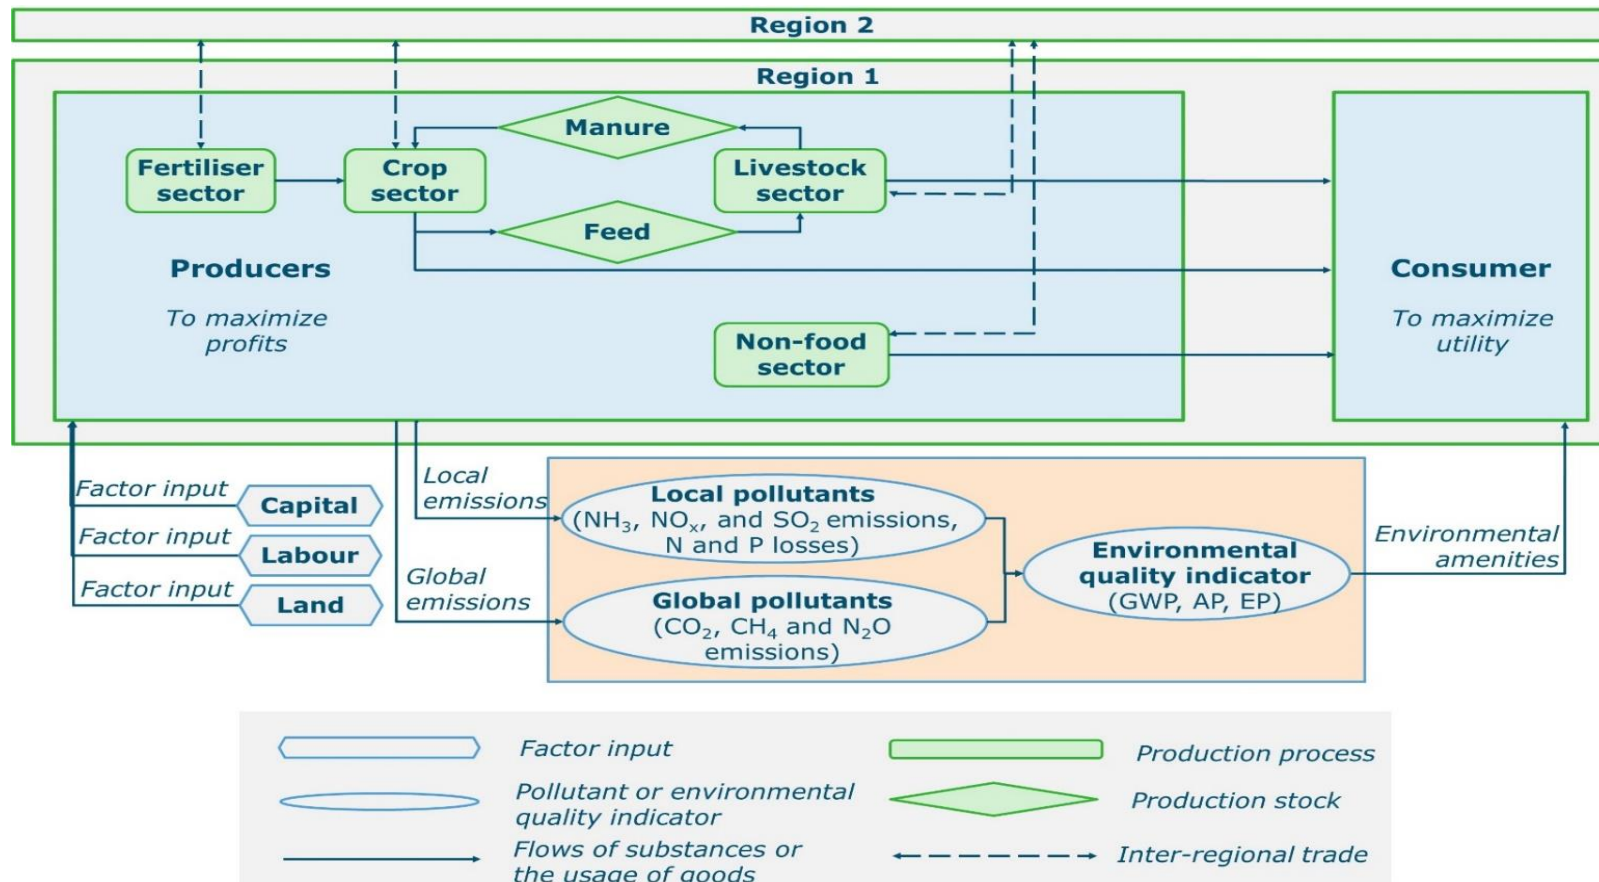

126 We developed a global comparative static AGE model, a modified version of an integrated
127 environmental-economic model (Zhu & Van Ierland, 2004, 2012; Zhu et al., 2006). The basic idea
128 of AGE models is that supply and demand are interconnected throughout the economy, such that
129 changes in one sector or market are transmitted to other sectors and markets. Our model incorporated
130 two major enhancements, which facilitate analysis of the food system. First, we enhanced the
131 representation of food-related (i.e., crop, livestock, soy-based food, and other food) and associated
132 non-food (compound feed, nitrogen fertiliser, phosphorous fertiliser, and non-food) sectors. Second,
133 we further added three main environmental impacts of food systems into the model, i.e., global
134 warming potential (GWP), acidification potential (AP), and eutrophication potential (EP). The
135 scheme of economy-wide environment impact assessment was provided in Fig. 1.

136 The objective of the model is to maximise the total social welfare of an economy subject to consumer
137 utilities, production technologies, commodity balances, and emissions affecting environmental
138 quality. In general, social welfare is a measure of overall well-being of society, including the
139 economic benefit (i.e., the consumption of goods) and environmental benefit (i.e., the amenity
140 values of the environmental quality) (Zhu & Van Ierland, 2006). AGE models can be presented in
141 various formats (Ginsburgh & Keyzer, 2002), all of which the same model and lead to the same
142 equilibrium solutions. We chose the Negishi format for our study because it is more effective in
143 addressing tipping points and non-convexities, similar to large-scale integrated assessment models
144 like the dynamic integrated climate-economy (DICE) model (Nordhaus, 1993). This is crucial for
145 addressing sustainability challenges, as many environmental issues involve non-convexities that
146 deviate from conventional economic assumptions. Additionally, the Negishi format of AGE models
147 is widely used to identify optimal options for greater sustainability, enabling efficient resource
148 allocation under social welfare maximisation (G. Fischer et al., 2007; Greijdanus, 2013; Keyzer &
149 Van Veen, 2005; Le Thanh, 2016; van Wesenbeeck & herok, 2006).

150

151 **Fig. 1.** Scheme of economy-wide environment impact assessment. The blue rounded squares depict the model itself. Parallelograms illustrate the inputs and outputs of
 152 the applied general equilibrium (AGE) model, which is calibrated using the Global Trade Analysis Project (GTAP) database. Green rectangles signify the base data
 153 used to evaluate various environmental impacts. Rounded squares with dotted lines indicate the different environmental impacts assessed. Arrows show the data flows
 154 within the model structure.

155

156 **Fig. 2.** Economic agents and material flows in the two-region environmental-economic framework. Region 1 is China, and region 2 encompasses the main food and
 157 feed trading partners (MTP, including Brazil, the United States, and Canada) of China. The two regions have the 'same' structural outline of the economy-environment
 158 interaction framework. GWP = global warming potential. AP = acidification potential. EP = eutrophication potential. CO₂ = carbon dioxide. CH₄ = methane. N₂O =
 159 nitrous oxide. NH₃ = ammonia. NO_x = nitrogen oxides. SO₂ = sulphur dioxide. N = nitrogen. P = phosphorus

160 We used the GTAP version 10 database (GTAP, 2014) based on general equilibrium theory to
161 calibrate our AGE model. It covers 65 sectors (agriculture, manufacturing, and services) of the
162 economy and 141 countries. For illustrative purposes, our model distinguishes two regions, namely
163 China and its main food and feed trading partners (MTP, including Brazil, the United States, and
164 Canada). Each region has one representative consumer who consumes rival goods and non-rival
165 environmental quality related to different types of pollutants (Fig. 2.). These trading partners
166 accounted for more than 75% of China's total trade volume related to food and feed in 2014. Our
167 reference year is 2014, which is the latest available year for data in the GTAP database. We designed
168 a sectoral aggregation scheme comprising 13 sectors (see Appendix Table B1) from the original
169 GTAP database to produce social accounting matrices (SAM) (see Appendix Tables B2 and B3) in
170 our study. Our sectoral aggregation scheme for GTAP ensured that all competing and
171 complementing sectors for food and feed were present in a disaggregated form. Factor endowments
172 (i.e., capital, labour, land) owned by consumers are mobile between different sectors but immobile
173 among the two regions according to the GTAP default settings. Producers produce goods with the
174 use of capital, labour, land, and intermediate goods. Products from the livestock and non-food
175 sectors are used for direct human consumption, while crop products are used as food for human
176 consumption and as feed for livestock production. Fertilisers and livestock manure are used for crop
177 production. The model is solved by the general algebraic modelling system (GAMS) software
178 package (GAMS, 2022). Further details about the model are presented in Supplementary
179 Information (SI).

180 To estimate changes in environmental dimensions, we established an economy-wide environmental
181 impact database for China and MTP in the baseline, rather than restricted in certain sectors within
182 the food system. Three main environmental impacts include GWP (caused by emissions of
183 greenhouse gases (GHGs), including carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O)
184 emissions; converted to CO₂ equivalents), AP (caused by emissions of acidification pollutants,
185 including ammonia (NH₃), nitrogen oxides (NO_x), and sulphur dioxide (SO₂) emissions; converted
186 to NH₃ equivalents), and EP (caused by emissions of eutrophication pollutants, including N and P
187 losses; converted to N equivalents). The conversion factors for GWP, AP, and EP are shown in Table
188 A.1. We obtained data on CO₂, CH₄, and N₂O emissions from the Climate Analysis Indicators Tool

189 (CAIT) (2014). We derived NH₃, NO_x, and SO₂ emissions from L. Liu et al. (2022), Huang et al.
190 (2017), and Dahiya et al. (2020), respectively. We considered NO_x emissions from energy use only,
191 as agriculture's contribution to NO_x emissions is generally small ($\leq 2\%$). We used the global
192 eutrophication database of food and non-food provided by Hamilton et al. (2018) to obtain data on
193 N and P emissions to water bodies. We first obtained the total emissions of GHGs, acidification
194 pollutants, and eutrophication pollutants for the food and non-food sectors in the base year. Then,
195 we allocated the total emissions to specific sectors according to the shares of emissions per sector
196 in total emissions to unify the emission data from different years. Emissions per sector were
197 calculated based on the emission database mentioned above and additional literature provided in SI
198 by multiplying the physical quantity of an activity undertaken (in tons) and the corresponding
199 emissions coefficient (tons of CO₂, NH₃, or N equivalents per unit of activity undertaken). The
200 sector-level emissions of GHGs (Tg CO₂ equivalents), acidification pollutants (Tg NH₃ equivalents),
201 and eutrophication pollutants (Tg N equivalents), as well as the US dollar-based emission intensities
202 of GHGs (t CO₂ equivalents million USD⁻¹), acidification pollutants (t NH₃ equivalents million
203 USD⁻¹), and eutrophication pollutants (t N equivalents million USD⁻¹), are presented in Table B4-6
204 and Table B7-9, respectively.

205 2.2 Scenarios

206 Differences in environmental concerns of consumers may cause negative environmental ‘spillover
207 effects’ (Hökby & Söderqvist, 2003; Latacz-Lohmann & Hodge, 2003; Zhu, 2004). The growing
208 environmental concerns over time are evidenced by the increasing environmental expenditures by
209 governments in high-income countries (Eurostat, 2020). Thus, we examined the impacts of
210 differences in environmental concerns of consumers in scenario 1 (S1), i.e., a two times higher
211 expenditure share for improving the environmental quality in MTP than in China. To explore options
212 for more sustainable food systems and to mitigate the negative environmental spillovers (in our case)
213 from MTP to China, we examined four additional scenarios regarding food consumption and
214 production as well as environmental policy, as follows: S2 - dietary structure change, i.e., doubling
215 soy-based food consumption while reducing pork consumption; S3 - cleaner cereals production
216 technology, i.e., adopting cleaner cereals production technology for half of the current resources

217 used for cereals production; S4 - combining dietary structure change with cleaner cereals production
218 technology (i.e., $S4 = S2 + S3$); and S5 - unilateral environmental policy in China, i.e., implementing
219 economy-wide taxes on emissions to contribute to China's emission reduction target and other
220 environmental policies. These scenarios were further described below and in Table A2 and SI. The
221 results of scenarios S2 to S5 were compared in relation to those of scenario S1, whereas scenario
222 S1 was evaluated relative to the baseline (S0). In S0, environmental quality indicators were set at
223 100 to facilitate the comparison of environmental quality changes across various scenarios. Thus, if
224 environmental quality indicators in scenarios are higher than 100, it means increases in
225 environmental quality (i.e., decreases in emissions) compared to S0.

226 2.2.1 Baseline (S0)

227 The baseline (S0) represents the economies of China and MTP in 2014. Environmental concerns of
228 consumers were not considered in S0 because the original GTAP database does not contain
229 expenditures on environmental programs for improving environmental quality. The substitution
230 elasticity between soy-based food (SBF) and pig (i.e., the ease of substituting pork with SBF for
231 consumption) was 0.5. The expenditure shares of SBF in the pork-SBF protein composite
232 consumption were 25% and 82% in China and MTP, respectively, as calculated based on the SAMs
233 from the GTAP database. These expenditure shares were maintained in all scenarios except for the
234 dietary shift scenario S2.

235 2.2.2 Differences in environmental concerns of consumers (S1)

236 Consumers in higher-income countries are more willing to pay for environmental quality than less
237 concerned countries (Hökby & Söderqvist, 2003; Latacz-Lohmann & Hodge, 2003). Environmental
238 concerns of consumers were reflected through their willingness to pay for environmental quality,
239 represented by the utility elasticity within the utility functions in our model. This implies that
240 consumers have to pay for their consumption of environmental quality. Environmental quality is
241 priced by the marginal value of a balance equation, where each individual's consumption equals the
242 total supply of the environmental quality. Environmental quality is “supplied” by the environment
243 and determined by the emissions of pollutants from all producers across the whole economy. Three
244 types of environmental quality indicators related to GWP, AP, and EP were determined in a linear

245 relationship by the associated equivalent emissions of pollutants. The higher the emissions, the
246 lower the environmental quality. Thus, emissions will decrease the utility of consumers by reducing
247 environmental quality. As the model accounts for both the utility from consuming goods and the
248 disutility from environmental pollution, consumers face a trade-off: increasing the consumption of
249 rival goods leads to lower environmental quality, whereas prioritising higher environmental quality
250 requires reducing the consumption of rival goods. In this manner, the emissions from production
251 give a feedback on utility and on the consumption bundle of rival goods and non-rival environmental
252 quality, indirectly influencing the production structure across the whole economy. That is,
253 consumers have the chance to improve environmental quality with reduced emissions due to their
254 cleaner food purchases. In S1, we assumed that consumers in China and MTP were willing to pay
255 1% and 2% of their total budget for improving environmental quality. Consumers in both regions
256 were assumed to be willing to pay equally for improving the three types of environmental quality
257 indicators related to GWP, AP, and EP as they attach equal importance to the three types of
258 environmental pollutants. Despite Brazil having a relatively lower gross domestic product (GDP)
259 and the United States and Canada having higher GDPs compared to China, we opted to aggregate
260 these three main trading partner countries as a whole. This decision was based on Brazil contributing
261 less than 10% to the combined GDP of these three countries, while the United States and Canada
262 account for over 90%, according to the GTAP database. Moreover, the simple two-region model
263 structure was employed here because some fundamental macroeconomic mechanisms can be better
264 understood in small and aggregated AGE models.

265 2.2.3 Dietary structure change (S2)

266 China is a major pork producer and consumer and a significant importer of animal-based products
267 (FAO, 2022). Pork consumption in China has exceeded the recommended red meat consumption
268 ranges reported by the EAT-Lancet diet (Willett et al., 2019) and the Chinese Dietary Guidelines
269 2022 (Chinese Nutrition Society, 2022). China is also the world's largest importer and consumer of
270 soybeans, which are utilised as both human food, including traditional SBF (tofu, soy milk, tempeh,
271 and soybean oil) and novel SBF (soy-based meat), and livestock feed (soybean meal) (FAO, 2022).
272 It has been shown that if consumers partially replace meat with plant-based food, GHG emissions,

273 land use, and water use can be reduced substantially (Aleksandrowicz, Green, Joy, Smith, & Haines,
274 2016; Guo, Shao, Trishna, Marinova, & Hossain, 2021; Tong et al., 2022; Yu, Jiang, Cheshmehzangi,
275 Liu, & Deng, 2023; M. Zhang et al., 2022). However, previous studies have not adequately
276 accounted for interactions with other sectors and countries, as they primarily focused on the
277 environmental impacts of dietary shifts within limited life cycles. It is crucial to consider these
278 interactions, as resources saved through dietary shifts may be reallocated elsewhere in the economy,
279 potentially mitigating the environmental benefits of the dietary shift. Aiking et al. (2006b) and
280 Markiewicz (2010) suggested that almost 50% of meat in the diet in terms of protein food
281 expenditure should be replaced by plant-based food in order to achieve a 20-fold reduction of
282 environmental pressure by 2035. In addition, from a nutritional perspective, the protein content in
283 SBF (13-19 grams per 100 grams) is comparable to that in traditional pork and beef (15 grams and
284 20 grams per 100 grams, respectively) (Yang, 2020). Thus, we explored the impacts of an exogenous
285 dietary shift in consumer demand, i.e., by doubling SBF consumption while reducing pork
286 consumption in China, driven by the increased consumer acceptance of SBF. The expenditure share
287 of SBF in the pork-SBF protein composite consumption increased from 25% in the baseline (S0) to
288 50% in S2 concomitant with a decreased pork consumption.

289 2.2.4 Cleaner cereals production technology (S3)

290 Interventions in cereals production technology are of interest for sustainable food production and
291 emission mitigation, as China is a major cereal producer, while fertilizer and pesticide inputs are
292 high (FAO, 2022; Zhai et al., 2021). Compared to China's original cereals production technology,
293 MTP's cereals production technology has a better technological performance (i.e., achieving the
294 same output level with fewer inputs) and requires relatively less land, labour, and nitrogen fertiliser
295 but more capital and phosphorus fertiliser to produce one unit of cereals. The cleaner technology
296 also has relatively lower emission intensities of all pollutants than the original technology (see Table
297 B7-9). Technological innovations have been well recommended in China, for example, through the
298 Science and Technology Backyard approach (Cui et al., 2018; W. Zhang et al., 2016). Therefore, in
299 S3, half of the current resource uses (i.e., capital, labour, land, nitrogen fertiliser, and phosphorus
300 fertilise) were employed using the cleaner MTP technology in cereal production. Technological

301 parameters and input cost shares of the two production technologies are presented in Table A3.

302 2.2.5 Combination of dietary structure change and cleaner cereals production technology (S4)

303 In S4, we combined the dietary structure change (S2) and cleaner cereals production technology (S3)
304 to examine to what extent the combination of demand-side and supply-side measures would affect
305 the economy (i.e., production, consumption, and trade) and environment (i.e., emissions of GHGs,
306 acidification pollutants, and eutrophication pollutants).

307 2.2.6 Unilateral environmental policy (S5)

308 The primary cause of environmental problems associated with food systems is emissions from
309 economic activities. Therefore, from a policy-making perspective, it is crucial to implement
310 effective measures, particularly economic instruments, to reduce emissions based on principles such
311 as the 'polluter pays principle'. A carbon tax, recognised as the most efficient market-based GHG
312 emission mitigation policy instrument, is highly recommended by economists and international
313 organisations (S. Frank et al., 2018; Lin & Li, 2011; Peña-Lévano, Taheripour, & Tyner, 2019; Zhu
314 et al., 2006). The introduction of economy-wide taxes on emissions would motivate producers and
315 consumers to shift from emission-intensive activities, commodities, and technologies to cleaner
316 alternatives. This is because if a producer's emission abatement cost is lower than the market price
317 for emissions, they will actively implement technological solutions to reduce emissions and sell the
318 excess emission quota to other sectors or regions. Thus, in a perfectly competitive world, emissions
319 are reduced most cost-effectively in sectors or regions with relatively high emission intensities or
320 significant mitigation potential. The emission tax can be determined based on the marginal value of
321 the emission permit balance equation, where total emissions from all producers across the whole
322 economy should not be above a certain level of emissions, thereby allowing the emission tax to be
323 imposed on the polluters. For the specified emission reduction target, the AGE model can
324 endogenously calculate the emission tax of different pollutants. The Chinese government has
325 committed itself to achieving carbon neutrality by 2060, in line with the Paris Agreement (NDRC,
326 2018). To accomplish this goal, China has pledged to reduce the country's carbon intensity
327 (emissions per unit of GDP) by more than 65% in 2030 compared to the 2005 level. The Chinese
328 government has also implemented several environmental policies to address nutrient losses from

329 agriculture and improve water quality. These policies include initiatives such as (i) Zero Fertilizer
330 Growth (MOA, 2015), (ii) Improvement of manure recycling (MOA, 2017), and (iii) Prevention
331 and Treatment of Water Pollution (“Ten-Point Water Plan”) (GOV, 2015). In this scenario, we
332 implemented economy-wide taxes on emissions to contribute to China's emission reduction target
333 and other environmental policies for a 3% reduction in emissions of all pollutants.

334 2.3 Sensitivity analysis

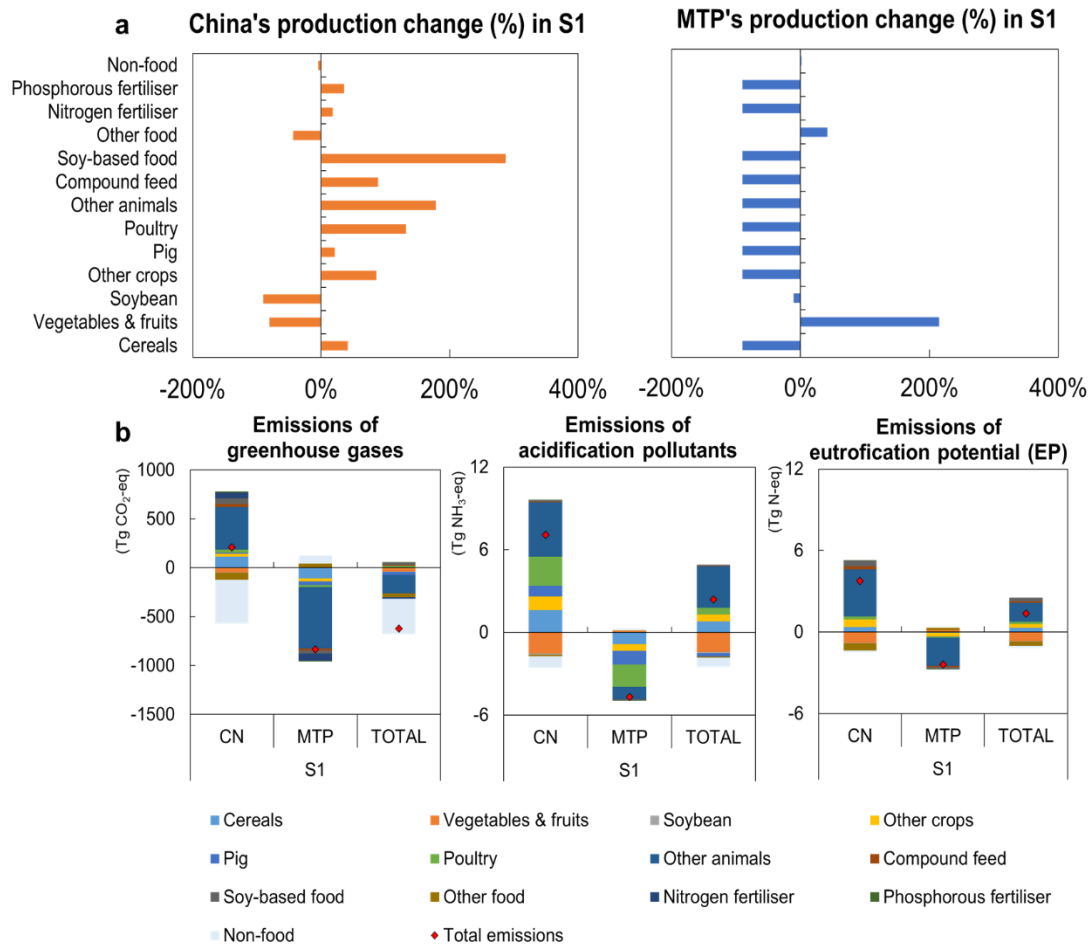

335 Conducting a sensitivity analysis is a way to check the robustness of a simulation model with many
336 uncertain parameters and the sensitivity of model results to these parameters. Results were obtained
337 for key environmental, economic behavioural, and technological parameters. So far, we have
338 assumed that current consumers were willing to pay equally for improving the three types of
339 environmental quality indicators related to GWP, AP, and EP. In the sensitivity analysis, we first run
340 the model by assuming that consumers were willing to pay for improving only one type of
341 environmental quality in both regions. Then, we increased the environmental willingness to pay in
342 China from 1% to 2%, equal to that in MTP. For the simultaneous reduction target of 3% for
343 emissions of all pollutants, we did sensitivity analyses for each type of pollutant. For the value of
344 the economic behavioural parameter, we considered the value of substitution elasticity between pork
345 and SBF in a range from 0.5 to 1.5 because SBF is not a perfect substitute for pork, and, in the short
346 run, it is impossible to replace all pork by SBF. For the value of the technological parameter, we
347 considered the value of the replacement ratio of cleaner MTP technology in a range of 0 to 1. Further
348 details about the sensitivity analysis are summarised in Table A4.

349 **3. Results**

350 3.1 S1 - Differences in environmental concerns of consumers

351 Differences in environmental concerns of consumers increased environmental quality indicators
352 related to GWP, AP, and EP in MTP relative to S0 by 10%, 34%, and 43%, respectively. Conversely,
353 these indicators experienced a 2% decrease in GWP, a 21% decrease in AP, and a 38% decrease in
354 EP in China (Table A5). The consumption of rival goods decreased by 0.06-4% in China and MTP
355 (Fig. A3.), as increasing environmental concerns in both regions call for reducing consumption of
356 rival goods. Despite the increased expenditure on environmental quality, the overall environmental

357 quality did not increase in China because the willingness to pay for improving environmental quality
358 was higher in MTP than in China (2% versus 1%). Consequently, emission-intensive production
359 was transferred from MTP to China (Fig. 3a), causing negative environmental spillovers from MTP
360 to China, i.e., increased emissions and lower environmental quality in China (Fig. 3b). To be more
361 specific, the production of goods with relatively high emission intensities, such as animal products,
362 soy-based food, and fertilisers, increased by 18-287% in China. The decline in the environmental
363 quality indicator associated with EP surpassed that of the other two indicators, primarily due to the
364 substantial increase in the production of other animals (179%) with high emission intensity of
365 eutrophication pollutants in China. In contrast, MTP obtained environmental benefits by decreasing
366 its domestic production of relatively emission-intensive products, as China increased production
367 and exported these goods to MTP. Concurrently, resources freed from the reduced production of
368 emission-intensive products were reallocated towards increasing the production of vegetables &
369 fruits by 215% and other food by 42% in MTP, respectively. This production shift is because MTP
370 has a comparative advantage in producing these relatively “clean” goods compared to China.

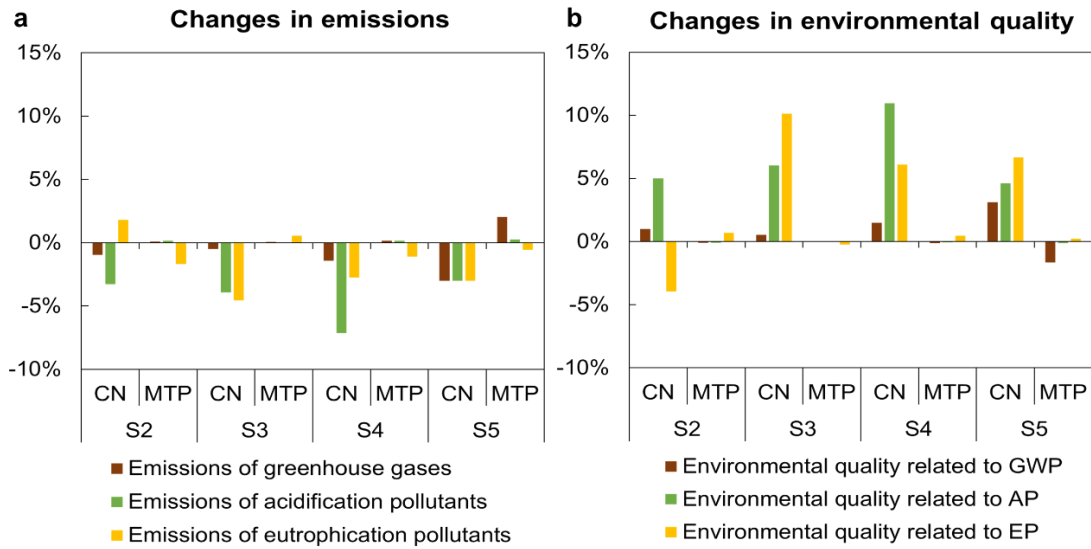

371

372 **Fig. 3.** Changes in (a) production of goods (%) and (b) emissions of greenhouse gases (Tg CO₂
 373 equivalents), acidification pollutants (Tg NH₃ equivalents), and eutrophication pollutants (Tg N
 374 equivalents) in China (CN) and its main trading partners (MTP) when there are differences in
 375 environmental concerns of consumers (S1). Changes are relative to S0.

376 3.2 S2 - Dietary structure change

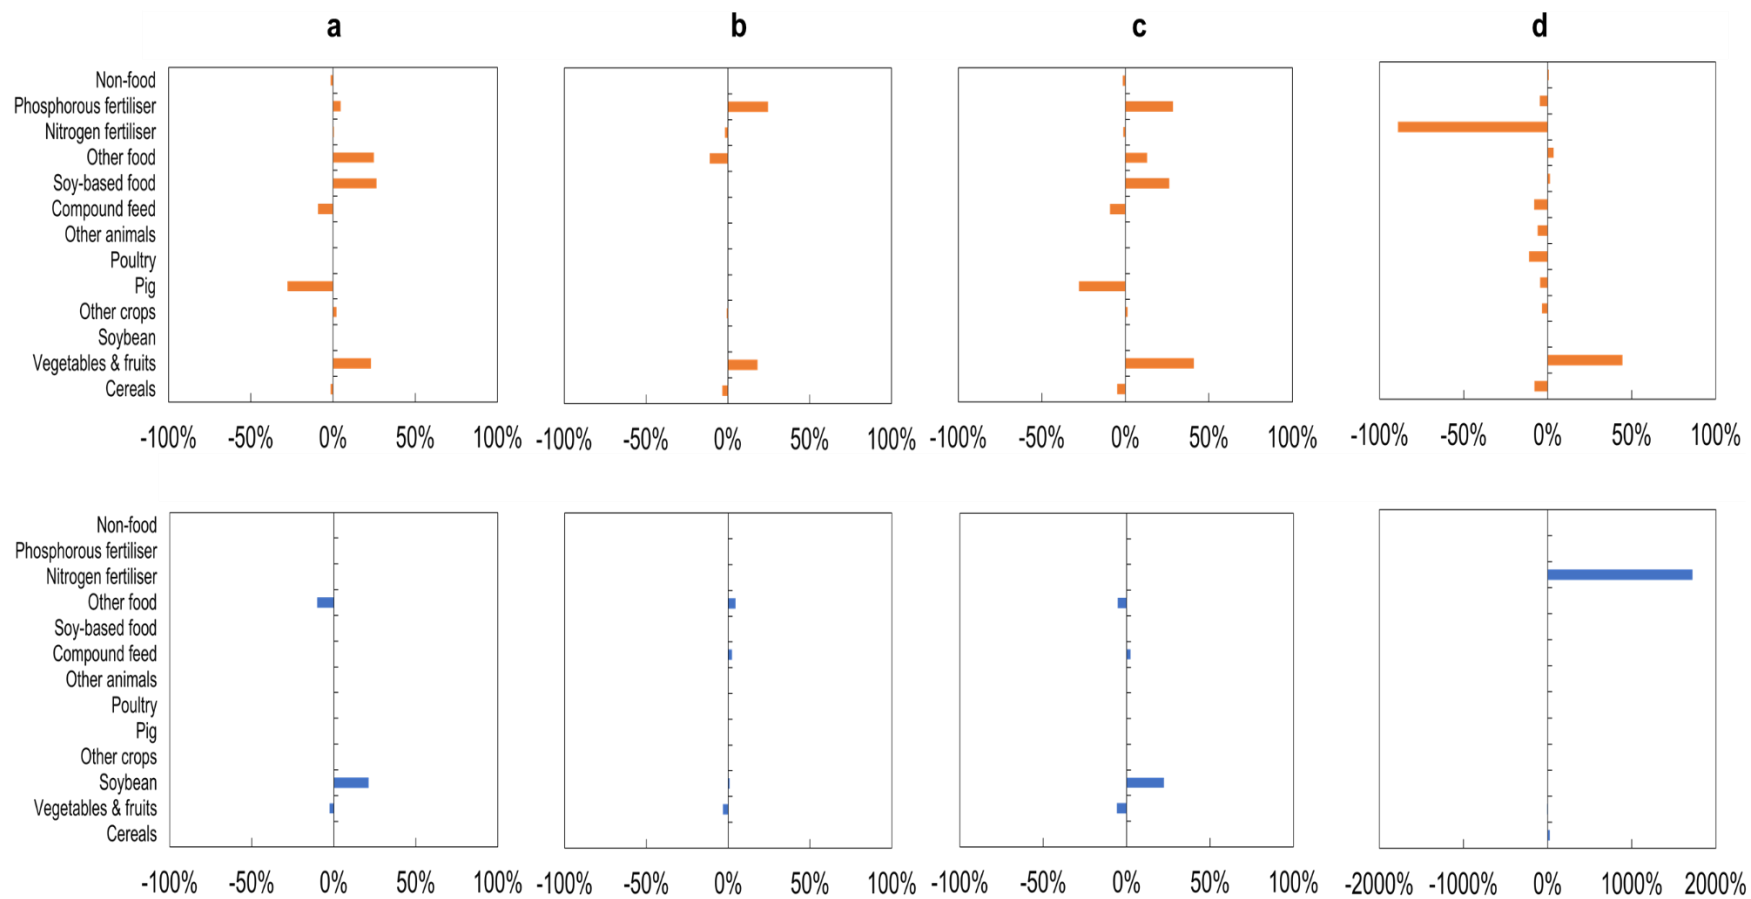

377 The dietary shift from pork to SBF decreased pork consumption by 33% and increased soy-based
378 food consumption by 102% in China (Fig. A4). This shift resulted in a 1% reduction in GHG
379 emissions and a 3% reduction in acidification pollutants, but a 2% increase in eutrophication
380 pollutants in China relative to S1 (Fig. 4 & 6). The latter increase in emissions was mainly propelled
381 by the heightened production of soy-based food and other food in China, which have relatively high
382 emission intensities of eutrophication pollutants.

383 Lower pork demand influenced not only the consumers and producers of pork but also have knock-
384 on effects on other sectors across the whole economy. Evidently, the reduction in domestic pork
385 consumption led to a 28% decrease in pig production (Fig. 5a), which subsequently reduced the
386 production of cereals (1%) and compound feed (9%) used to raise pigs. Agricultural inputs freed up
387 from reduced pig production were primarily reallocated to increase the production of plant-based
388 alternatives, such as soy-based food (26%) and other (crop-based processed) food (25%). Soybean
389 production in China remained nearly constant, as increased food use outweighed the decline in feed
390 use, with higher demand met by imports from MTP, where production surged by 21% due to MTP's
391 comparative advantage. The production of vegetables & fruits (23%) and other crops (2%) increased
392 in China due to their increased use as intermediate inputs for other (crop-based processed) food
393 production. Changes in China's crop production structure increased domestic fertiliser demand,
394 raising domestic production of nitrogen and phosphorus fertiliser by 0.5% and 5%, respectively.

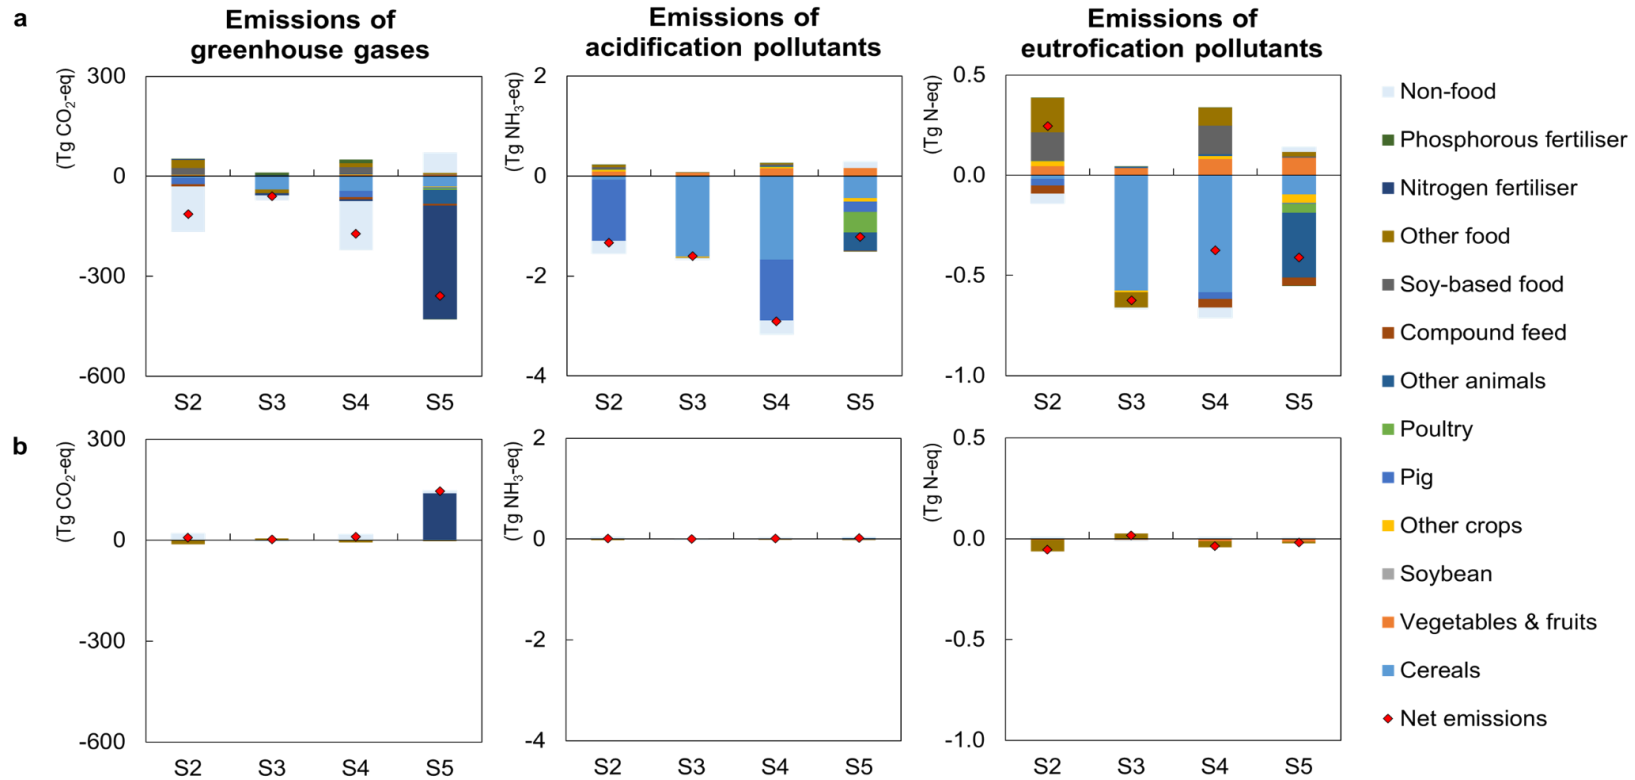

396

397 **Fig. 4.** Changes in (a) emissions of greenhouse gases, acidification pollutants, and eutrophication
 398 pollutants and (b) environmental quality indicators related to global warming potential (GWP),
 399 acidification potential (AP), and eutrophication pollutants (EP) in China (CN) and its main trading
 400 partners (MTP) under scenarios of dietary structure change (S2), cleaner cereals production
 401 technology (S3), the combination of dietary structure change and cleaner cereals production
 402 technology (S4), and unilateral environmental policy (S5). Changes are relative to S1, in %.

403

404 **Fig. 5.** Changes in the production of goods in China (upper panels) and its main trading partners (MTP, lower panels) under scenarios of (a) dietary structure change
 405 (S2), (b) cleaner cereals production technology (S3), (c) the combination of dietary structure change and cleaner cereals production technology (S4), and (d)
 406 unilateral environmental policy (S5). Changes are relative to S1, in %.

409 **Fig. 6.** Changes in emissions of greenhouse gases (Tg CO₂ equivalents), acidification pollutants (Tg NH₃ equivalents), and eutrophication pollutants (Tg N equivalents)
 410 in (a) China (upper panels) and (b) its main trading partners (MTP, lower panels) under scenarios of dietary structure change (S2), cleaner cereals production technology
 411 (S3), the combination of dietary structure change and cleaner cereals production technology (S4), and unilateral environmental policy (S5). Changes are relative to S1.
 412 The red dots in the figures refer to the net emissions in China and MTP, respectively.

413 3.3 S3 - Cleaner cereals production technology

414 Adoption of cleaner cereals production technology in China decreased emissions of GHGs,
415 acidification, and eutrophication pollutants in China by 0.5%, 4%, and 5%, respectively, relative to
416 S1 (Fig. 4 & 6). In addition, the adoption of cleaner technology, which requires relatively less
417 nitrogen fertiliser but more phosphorus fertiliser to produce one unit of cereals than the original
418 technology, resulted in a 2% decrease in nitrogen fertiliser production and a 25% increase in
419 phosphorus fertiliser production (Fig. 5b.). This adoption also led to a 3% decrease in cereals
420 production, as the higher costs of increased capital and phosphorus fertiliser use outweighed the
421 savings from reduced land, labour, and nitrogen fertiliser use. The higher production cost of cereals
422 increased cereal prices, resulting in a 3% decrease in cereals consumption in China (Fig. A4.).
423 Higher cereal prices also led to an 11% decrease in the production of other (crop-based processed)
424 food, which rely on cereals as intermediate inputs. Consequently, resources freed as a result of
425 adopting cleaner cereal production technology were reallocated, resulting in an 18% increase in
426 vegetables & fruits production in China and a corresponding decrease in imports from MTP. The
427 structural shifts in China's production also have cross-border impacts, influencing production in
428 MTP through international trade. Specifically, the production of vegetables & fruits in MTP declined
429 by 3%, whereas the production of other food increased by 4%.

430 3.4 S4 - Combination of dietary structure change and cleaner cereals production technology

431 Combining dietary changes with cleaner cereals production technology in China decreased
432 emissions of GHGs, acidification, and eutrophication pollutants in China by 1%, 7%, and 3%,
433 respectively, relative to S1 (Fig. 4 & 6). That is, the combination decreased the pollution-swapping
434 effect associated with the dietary shift scenario. This combination resulted in a 5% reduction (2%
435 more than S3) in cereal production in China (Fig. 5c), attributed not only to its increased production
436 costs but also to decreased demand for cereals as feed in the pig sector. Resources freed up by this
437 combination were reallocated, leading to a 41% increase in vegetables & fruits production, along
438 with a 13% increase in the production of other food in China. In contrast, the production of
439 vegetables & fruits and other food in MTP decreased by 6% and 5%, respectively.

440 3.5 S5 - Unilateral environmental policy

441 Implementing a unilateral environmental policy in China (i.e., implementing economy-wide taxes
442 on emissions to reduce emissions of all pollutants by 3%) increased emissions of GHGs by 2% in
443 MTP with minor impacts on emissions of acidification and eutrophication pollutants relative to S1
444 (Fig. 4 & 6). The increased GHG emissions in MTP reflect the so-called 'carbon leakage'. This
445 emerges due to the shift of production of products with relatively high emission intensities from
446 China to MTP as there were no emission restrictions in MTP. For example, China experienced
447 reductions in the production of cereals by 8%, other crops by 3%, pigs by 5%, poultry by 11%, other
448 animals by 6%, nitrogen fertiliser by 90%, and phosphorus fertiliser by 5% (Fig. 5d). The percentage
449 change in nitrogen fertiliser production was the most significant because nitrogen fertiliser
450 production has high GHG emission intensity (see Table B7). Therefore, to reduce economy-wide
451 GHG emissions in China, the highest priority should be placed on reducing nitrogen fertiliser
452 production and use. The consumption of goods with relatively high emission intensities also
453 decreased by 2-10% (refer to Fig. A4), as these "dirty" goods became relatively more expensive due
454 to emission restrictions. Meanwhile, China increased the production of products with relatively low
455 emission intensities, such as vegetables & fruits (45%). Although the fertiliser application rate per
456 hectare is about two folds higher for vegetables & fruits than for cereals and soybean (Wang et al.,
457 2021), the dollar-based emission intensities of all pollutants are relatively low for vegetables & fruits
458 (see Table B7-9), which is related to the high prices and yields of vegetables & fruits (FAO, 2022).
459 In contrast, due to MTP's comparative advantage in nitrogen fertiliser production, its output
460 increased by 17 times. The substantial percentage changes in nitrogen fertiliser production can be
461 attributed to its initially low share of value-added in MTP's GDP.

462 3.6 Sensitivity analysis

463 Alterations in model results were examined in responses to variations in the values of three
464 parameters: environmental concerns, the substitution elasticity between pork and SBF, and the
465 replacement ratio of the cleaner cereals production technology.

466 First, if consumers only care about one type of environmental quality, the gap between countries
467 with different environmental concerns in that type of environmental quality is larger than the gap in

468 the other two types of environmental quality (Table A5). When countries have equal environmental
469 concerns, the gaps in environmental quality, particularly related to EP, diminish between China and
470 MTP (Table A6). Furthermore, a single emission reduction target for China would improve one type
471 of environmental quality at the expense of the other one or two types (Table A7).

472 Second, for the substitution elasticity between pork and SBF, the current value was 0.5. Variation in
473 the elasticity in the range of 0.5 to 1.5 did not affect pork consumption under S2 (Fig. A8a) because
474 the expenditure share of SBF in the pork-SBF composite consumption remained fixed. However, a
475 higher substitution elasticity indicates an increased price ratio between SBF and pork, leading to
476 decreased pork production as pork becomes cheaper (Fig. A8b).

477 Third, increasing the replacement ratio of the cleaner cereals production technology in China
478 decreased cereals production, as well as emissions of all pollutants (Fig. A9). Specifically, raising
479 the technology replacement ratio from 0% to 40% resulted in a significant decrease in cereals
480 production. This is because the cleaner MTP technology necessitates relatively less land, labour, and
481 nitrogen fertiliser but more capital and phosphorus fertiliser to produce one unit of cereals.
482 Reallocating resources raises production costs, as the higher costs of increased capital and
483 phosphorus fertiliser use outweigh savings from reduced cropland, labour, and nitrogen fertiliser
484 use, leading to reduced cereal production. When the ratio exceeded 40%, the model results for
485 cereals production stabilised, reaching a point where no additional capital and phosphorus fertiliser
486 would be available for cereals production. Overall, changes in model parameters had a modest
487 impact on model results, showing the robustness of the model results.

488 **4. Discussion**

489 4.1 Main findings

490 Our study emphasises the importance of employing an economy-wide modelling approach, rather
491 than a single sector/country approach, in the design of effective policies for sustainable food systems.
492 This broader perspective enables a deeper understanding of the interconnections among different
493 countries, sectors, and environmental impacts, while also shedding light on the trade-offs between
494 environmental and economic objectives.

495 First, we found that differences in environmental concerns of consumers led to cross-national
496 pollution spillover effects through international trade, a type of telecoupled impact (Hull & Liu,
497 2018; J. Liu, 2023). Specifically, environmental quality increased more in countries with higher
498 environmental concerns compared to those with lower concerns because the production of 'dirty'
499 products shifted to countries with lower environmental concerns through international trade. This
500 echoes findings by Meyfroidt, Lambin, Erb, and Hertel (2013), who argue that globalisation can
501 benefit developing nations economically but can also lead to negative environmental impacts like
502 carbon leakage and land-use displacement. Our study focused on emissions of GHGs, acidification,
503 and eutrophication pollutants, rather than solely on a specific environmental impact (mainly GWP),
504 as previous studies have done using models such as GTAP-E (Burniaux & Truong, 2002), GTAP-
505 AEZ (Lee, 2005), and GTAP-BIO (Golub & Hertel, 2012). This is significant because food systems
506 contribute more to these pollutants than to GHGs (Aiking et al., 2006a; Galloway, 2001; Leip et al.,
507 2015; Xue & Landis, 2010), yet no studies have explored this aspect within the AGE framework so
508 far. This 'spillover effect' in our study shows that China experienced a decrease of 2%, 21%, and 38%
509 in environmental quality indicators related to GWP, AP, and EP, while MTP experienced an increase
510 of 10%, 34%, and 43%, respectively. It indicates that the production of goods with high emission
511 intensities of eutrophication pollutants was swapped more from MTP to China than those with high
512 emission intensities of GHGs and acidification pollutants.

513 Second, our results show that shifting towards a more soy-based diet could reduce GHG emissions
514 due to the higher human-edible energy and protein conversion efficiencies of plant-based foods
515 compared to animal products (Eshel et al., 2018; Yu et al., 2023; M. Zhang et al., 2022). Additionally,
516 it has been estimated that a dietary shift towards more plant-based food in China increases total
517 human-edible energy (3-20 times) and protein (1-5 times) deliveries while reducing carbon and
518 nitrogen footprints (Long et al., 2021). A key novel insight of our study is that the reductions in
519 GHG emissions were partially attenuated by increased production in other sectors, such as SBF
520 (26%) and other food (25%). Agricultural inputs, including capital, labour, land, and primary feed
521 (mainly cereals and compound feed), freed up from reduced pig production, were reallocated within
522 the Chinese food system. Relocation of resources across the food system enables more production
523 with the same inputs (increased efficiency), but may attenuate the expected outcome in terms of

524 emission reductions and does not guarantee a decline in total resource use. Specifically, our study
525 showed that the dietary shift from pork to SBF decreased economy-wide emissions of GHGs by 1%
526 and acidification pollutants by 3% but increased emissions of eutrophication pollutants by 2% in
527 China. This is because the interlinkages between production sectors were captured in our integrated
528 environmental-economic framework, and, as a result, we identified the increased production of SBF
529 and other food with relatively high emission intensities of eutrophication pollutants through resource
530 reallocation. Hamilton et al. (2018) confirmed this by showing that processed food sectors, such as
531 SBF and other food, are major contributors to eutrophication, accounting for 19% and 10.3% of
532 global marine and freshwater eutrophication impacts, respectively. Furthermore, changes in China's
533 crop production structure led to a 0.5% rise in nitrogen fertiliser production and a 5% increase in
534 phosphorus fertiliser production domestically. Recently, Mason-D'Croz et al. (2022) assessed the
535 economy-wide impact of adopting plant-based beef substitutes, demonstrating reduced economy-
536 wide GHG emissions and increased fertiliser use in the USA. Our analysis goes further by using a
537 global model, rather than a national one, to consider the cross-border impacts on trading partners
538 through international trade. For instance, our model showed a 21% increase in soybean production
539 in MTP, driven by its comparative advantage in soybean production over China. Additionally, our
540 comprehensive assessment of emissions of GHGs, acidification, and eutrophication pollutants
541 enables us to discern trade-offs and synergies associated with each type of emission.

542 Third, we provide possible solutions to prevent the pollution-swapping effect associated with the
543 dietary shift scenario. Our analysis illustrated that both combining a dietary shift with cleaner cereals
544 production technology and implementing a unilateral environmental policy (i.e., implementing
545 economy-wide taxes on emissions) decreased emissions of all pollutants in China. However,
546 implementing unilateral environmental policies in China could cause the so-called 'carbon leakage'
547 (Kuik & Gerlagh, 2003). On the one hand, it decreased emissions in China by reducing domestic
548 production of goods with high emission intensities of GHGs (e.g., nitrogen fertiliser), acidification
549 pollutants (e.g., cereal, pig, poultry, and other animals), and eutrophication pollutants (e.g., other
550 animals). On the other hand, it also increased emissions of GHGs in MTP with minor impacts on
551 emissions of acidification and eutrophication pollutants.

552 4.2 Policy implications

553 Our study provides insights into minimising the trade-offs and exploiting the synergies in the food-
554 land-water-climate nexus. This is crucial for achieving sustainable food production and
555 consumption not only in China but also in other developing countries similar to China facing similar
556 challenges in food production in the context of globalisation and international trade. Therefore, our
557 findings hold the following policy implications.

558 First, our findings show that developed countries typically gain environmental benefits at the
559 expense of developing countries, which bear the environmental burdens through international trade.
560 This is partly because higher environmental concerns among consumers and stringent regulations
561 in developed countries tend to shift emission-intensive production to developing countries
562 (Wiedmann et al., 2015; Xu et al., 2020). The 'spillover effects' caused by differences in
563 environmental concerns of consumers cannot be ignored as such effects could hinder the
564 environmental quality of countries with lower environmental concerns. Our analysis shows that
565 when countries have equal environmental concerns, the gaps in environmental quality, particularly
566 concerning EP, diminished between China and MTP. Therefore, it is essential to bridge the gap
567 between consumers in countries with different environmental concerns.

568 Second, our economy-wide analysis shows that the environmental benefits of the dietary shift from
569 pork to SBF were smaller than previous narrower studies have estimated (Eshel et al., 2018; Long
570 et al., 2021; Yu et al., 2023; M. Zhang et al., 2022). This is because resources freed up from pig
571 production were repurposed for other economic activities, such as intensifying soybeans used as
572 inputs for soy-based food production. This underscores the risks of policies focusing on a single
573 sector and the need for comprehensive policies to address potential spillover effects on food systems
574 and the broader economy. China has a long history of soy-based protein food, with traditional SBF
575 (tofu, soy milk, tempeh, and soybean oil) dating back thousands of years. While novel SBF (soy-
576 based meat) differ in flavour, both derive from soybeans, creating a strong foundation for market
577 growth (Academy of Global Food Economics and Policy, 2024). However, shifting dietary habits in
578 China is challenging to achieve in the short run (Bai et al., 2018), since pork consumption is a
579 culture-related issue. There is a need to promote environmental concerns among consumers and

580 provide information about the environmental benefits of SBF for sustainable food consumption and
581 production. Advertising campaigns and providing consumers with carbon labels linked to the life
582 cycle of food can enhance environmental concerns among consumers (Aiking et al., 2006b;
583 Camilleri, Larrick, Hossain, & Patino-Echeverri, 2019). Additionally, providing food labels that
584 inform consumers about the health benefits of products they purchase, in addition to their
585 environmental advantages, can also motivate the dietary shift (Markiewicz, 2010). Technological
586 improvements in taste, texture, and variety (Bonny, Gardner, Pethick, & Hocquette, 2017; Megido
587 et al., 2016; Verbeke, Sans, & Van Loo, 2015), along with price mechanisms such as meat tax or
588 lower prices for meat substitutes (Latka et al., 2021) could encourage the dietary shift. Promoting
589 dietary guidelines, carbon taxes, and environmentally friendly behaviours can also help reduce meat
590 consumption and GHG emissions (Bonnet, Bouamra-Mechemache, Réquillart, & Treich, 2020; C.
591 G. Fischer & Garnett, 2016).

592 Third, we demonstrate that adopting cleaner cereals production technology in China can mitigate
593 emissions of all pollutants but demands capital reallocation from other sectors. Climate change
594 agreements could incorporate technology transfer and support initiatives to encourage the
595 widespread adoption of cleaner production technologies (S. Frank et al., 2018). Additionally, policy
596 instruments such as agricultural subsidies could expedite the adoption of cleaner production
597 technologies (Springmann & Freund, 2022).

598 Fourth, our study indicate that the unilateral environmental policy (i.e., implementing economy-
599 wide taxes on emissions) in China can lead to ‘carbon leakage’ by outsourcing the production of
600 emission-intensive goods to MTP. The global effects of this leakage depend on emission intensities
601 across regions. Avetisyan, Hertel, and Sampson (2014) contend that reducing emissions of GHGs
602 through consumption diversion to local goods is only achievable in regions with relatively low
603 emission intensities. Policymakers should carefully consider the consequences of implementing
604 unilateral environmental policy as it might inadvertently redirect economic activities in ways that
605 exacerbate environmental pressures elsewhere. Restricting imports of emission-intensive goods
606 alongside domestic emission restriction policy could avoid emission leakages to other countries
607 (Shammin & Bullard, 2009). In addition, a globally coordinated mitigation policy could also buffer

608 the emission leakages caused by the unilateral environmental policy (Stefan Frank et al., 2021).
609 Thus, achieving sustainable food production and consumption requires joint efforts from consumers
610 and producers as well as coordinated environmental policy across countries in the world.

611 4.3 Limitations of the study

612 Our model, like all AGE models, simplifies reality and operates at a high level of aggregation, which
613 may limit its ability to represent an economy out of equilibrium and primarily view behaviour
614 through an economic lens. Further, the linear relationship between emissions and environmental
615 quality indicators in our model is a simplified representation of real world. Also, our study assumes
616 free international trade, full mobility of factor endowments (capital, labour, and land) across sectors,
617 and constant income elasticities for all consumption goods. Neglecting trade barriers may
618 overestimate the extent of international trade of feed and food. Barriers to the movement of factor
619 endowments across sectors could be included, for example, by introducing separate labour and
620 capital markets for agricultural and non-agricultural sectors or allowing for land shifts within
621 agroecological zones with similar soil, landform, and climatic features, as demonstrated by the
622 MAGNET (Woltjer et al., 2014) and GTAP-AEZ (Lee, 2005) models. Last but not least, our static
623 model, which does not consider technological and resource changes over time, limits its
624 applicability to short-term policy analysis. A dynamic AGE model (Babatunde, Begum, & Said,
625 2017) may help to better understand the food systems in the context of climate change. Despite these
626 limitations, AGE models are among the best tools currently available for assessing the economy-
627 wide effects of policy changes and shock events in society. While AGE models may not capture the
628 internal technology flow or operational processes within specific sectors, they facilitate bridging the
629 micro- and macroscopic agents to understand the trade-offs between environmental and economic
630 objectives within the food-land-water-climate nexus by fully considering the teleconnections of
631 different sectors and regions. Thus, our study offers valuable insights into the complex policy effects
632 across the whole economy.

633 **5. Conclusions**

634 In our study, we discussed how differences in environmental concerns of consumers could cause
635 'spillover effects' of emissions, namely, from trading partners with higher environmental concerns

636 to China. We further explored options for more sustainable food systems with minimal spillover
637 effects by simulating a partial dietary shift from pork to soy-based food, cleaner cereal production
638 technology, and unilateral emission restrictions.

639 Differences in environmental concerns of consumers greatly influenced production patterns and
640 emissions. The environmental quality increased more in trading partners with high environmental
641 concerns than China because the production of ‘dirty’ products was transferred to China through
642 international trade. This ‘spillover effect’ was noted for emissions of all pollutants.

643 A partial dietary shift from pork to soy-based food in China decreased emissions of GHGs and
644 acidification pollutants but increased emissions of eutrophication pollutants because of the increased
645 production of SBF and other (crop-based processed) food in China. Adoption of cleaner cereals
646 production technology in China decreased emissions of all pollutants but required capital
647 reallocation from other sectors. Combining a dietary shift with cleaner cereals production
648 technology decreased emissions of all pollutants further and also decreased the pollution swapping
649 from MTP to China. Implementation of unilateral emission restrictions in China caused ‘carbon
650 leakage’ to MTP, as nitrogen fertiliser and livestock production were transferred from China to MTP.
651 Evidently, achieving sustainable food production and consumption requires joint efforts from
652 consumers and producers as well as coordinated environmental policy across countries in the world.

653 **Author contribution statement**

654 W.L., X.Z., H.P.W., O.O., and Y.H. designed the research; W.L. and X.Z. developed the model; W.L.,
655 X.Z., O.O., and Y.H. analysed data; W.L., X.Z., H.P.W., O.O., and Y.H. wrote the paper. All authors
656 contributed to the analysis of the results. All authors read and commented on various drafts of the
657 paper.
